Abstract

As biomedical data continues to grow at an unprecedented rate, the need to provide an integrated biomedical knowledgebase for drug discovery remains a major challenge. One of the limiting factors in any data integration effort is *entity resolution* (ER), i.e., the ability to determine which entities from different data sources with shared partial (and perhaps even inconsistent) identities are equivalent. For many entity types with well-defined nomenclature (e.g., gene, protein, cell line, etc.), ER amounts to simple identifier lookups. For drug entity type, however, ER is rather challenging due to ambiguities in how it is defined and represented. Herein we report on our recent effort to develop an ER framework, STITCHER, for drug data integration that addresses the shortcomings of traditional ER approaches. Using *active moiety* as the defining semantic concept for drug entity, we develop a set of equivalence relations (i.e., *stitch keys*) in STITCHER that specifically address ER for drug entities. We demonstrate the utility of our approach through the development of a comprehensive resource, INXIGHT DRUGS (`https://drugs.ncats.io`), of drugs that have either been marketed or approved in the United States for human use. To the best of our knowledge, this resource is currently the most comprehensive of its kind. The source code for STITCHER is readily available at `https://github.com/ncats/stitcher`.

Keywords: entity resolution; drug database; data integration

Introduction

As the volume of biological data continues to grow at an unprecedented rate [1], data de-duplication—also commonly known as *record linkage* [2] or *entity resolution*—is proportionally playing a prominent role in data integration. From the construction of training data for machine learning to building knowledge graphs as epistemological frameworks for artificial intelligence, proper entity resolution (ER) is essential in creating ground-truth data and turning data into knowledge. The core challenge of ER is in establishing *equivalence* between entities. For well-defined entity types (e.g., gene, tissue, cell line), this is often determined solely based on established identifiers and nomenclature; for other entity types (e.g., drug, disease, phenotype), however, equivalence is not as well-established due to conceptual ambiguities in how entities are defined and represented. Take disease as an example; the discrepancy between the theoretical concept of "disease entity" from its clinical nosology [3] is what makes disease ER extremely challenging.

Drug is another entity type that is also challenging for ER due to ambiguities in its definitions and representations. While the word is included within the name of

the organization, the U.S. Food and Drug Administration (FDA) does not have a straightforward definition of the word "drug." The Federal Food Drug and Cosmetic Act (FD&C Act) and FDA regulations define the term drug, in part, by reference to its intended use, as "articles intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease" and "articles (other than food) intended to affect the structure or any function of the body of man or other animals" [4]. More practically, the agency defines "drug substance" and "drug product," respectively, as the physical ingredients found in marketed products. Others use the word "drug" to sometimes refer to "drug substances" and sometimes to "drug products" as convenient, and this causes a great deal of semantic confusion within drug data found on the internet. The National Library of Medicine produces a semantic product, RxNorm, that provides a variety of precise semantic types for ingredients, tradenames, dose forms, semantic clinical drug components, semantic clinical drug forms, and semantic clinical drugs which facilitate working with drug data, but its terminology is unfortunately limited to commonly used prescription drugs, "clinically significant ingredients," and adoption of this complex semantic scheme is limited [5].

There is a third definition of the word "drug" that is commonly used in the literature and used by the FDA when it refers to an active moiety and a new molecular entity. In this case, ingredients whose pharmacological effect occurs through the same molecular entity are considered the same drug. This holds for different salt forms such as Sumatriptan Succinate and Sumatriptan Hemisulfate, but it also holds for prodrugs and their metabolized active forms such as Brincidofovir and Cidofovir [6]. The FDA defines *active moiety* as follows:

> An active moiety is a molecule or ion, excluding those appended portions of the molecule that cause the drug to be an ester, salt (including a salt with hydrogen or coordination bonds), or other noncovalent derivative (such as a complex, chelate, or clathrate) of the molecule, responsible for the physiological or pharmacological action of the drug substance [7].

Under the Food and Drug Administration Amendments Act of 2007, all newly introduced active moieties must first be reviewed by an advisory committee before the FDA can approve these products. We adopt this defintion throughout the paper.

As in other information domains, the names used to refer to drug substances and products are particularly problematic because their definitions change as a function of location or jurisdiction, time and context. FDA and other national regulators of medicines have collaborated to produce ISO 11238 [8] which endeavors to define an information scheme for the unambiguous identification of all ingredients found in medicinal products, and FDA uses an implementation of ISO 11238 as the backbone of its information systems within the agency [9]. While this facilitates data exchange within the FDA and with other national authorities, the task still remains to be able to map other, external data sources into this rigorously-defined scheme using whatever names and data are at hand.

Entity resolution (also known as *record linkage* in the literature) is the problem of determining which entities with partially shared attributes are equivalent across data sources. This is a fundamental challenge in data integration, and one that has

been an active area of research since the early days of computing [10]. Within the biomedical community, ER has been particularly instrumental in the analysis of electronic health records (EHRs) [11]. In the context of drug discovery, however, ER has received little attention; to our knowledge, the work by Croset et al. toward a drug product terminology [12] is the only recent effort that directly addressed ER. Here, the authors utilized graph density and betweeness centrality metrics to merge and identify problematic entities for each connected component within the link graph. The lack of available data and code, however, prevents further evaluation of their approach.

Herein we report on our effort to develop a robust ER framework, STITCHER, for drug data integration. By leveraging the semantic concept of *active moiety* and other well-defined attributes (e.g., molecular hash keys), we reduce the ER problem to that of establishing equivalence relations over a prioritized set of attributes (i.e., *stitch keys*). We demonstrate the utility of STITCHER toward a comprehensive data integration effort of drugs that have either been marketed or approved in the United States for human use. The INXIGHT DRUGS resource `https://drugs.ncats.io`, to the best of our knowledge, is currently the most comprehensive of its kind.

Preliminaries

As a motivating example, consider the data shown in Table 1. This table illustrates a common scenario where we would like to integrate data from multiple sources such that each data source might contain only partial (and possibly conflicting) information regarding the identities of the entities. There are four possible attributes that can be used to assert equivalence for the entities in this table, with the attribute `Structure` indicates whether the entity is associated with a chemical structure and that it possibly contains errors (e.g., missing or incorrect stereo assignments). Based on the definition of "drug" as defined above, we would like to determine the number of unique drugs that are there in the table. Examining the table, we can immediately make the case for three equivalence classes $\{A_4, B_2\}$, $\{A_3, C_2\}$, and $\{A_2, C_3\}$. We also know that A_3 is an active moiety of A_4 per our definition; through transitive closure, we now have the following equivalence classes: $\{A_4, B_2, A_3, C_2\}$ and $\{A_2, C_3\}$. (We should note here this active moiety relationship is rather trivial in that it can be inferred algorithmically, whereas active moiety relationships that involve metal complexes and non-trivial metabolites are likely to require manual curations.) Continue to perform transitive closure on the shared attributes in order, we eventually arrive at the final three equivalence classes $\{A_1, A_2, B_1, C_3, D_1, D_3\}$, $\{C_1\}$, and $\{A_3, A_4, B_2, C_2, D_2, E_1\}$, which correspond to three distinct isomers (*S*-, *R*-, and racemic, respectively) of the drug OMEPRAZOLE. (Note that the *R*-isomer is not an approved drug.)

The goal of ER, as shown by the above example, is to partition entities within a given dataset into disjoint sets such that those within the same set are considered equivalent. To achive this, STITCHER first "stitches" together entities with shared identity attributes (i.e., *stitch keys*). Next, transitive closure is performed based on heuristics that we have developed in assigning priorities to the stitch keys. And finally equivalence classes are efficiently derived through standard union-find algorithm [13]. This is the essence of STITCHER.

Core concepts

The conceptual data model underlying STITCHER is a *multigraph*. Within this multigraph, a node can either be a *stitch node* or *data node*. Each data node represents the "raw" entity as ingested from the data source; its corresponding stitch node is a *standardized* representation that is used for *stitching*. An edge between two stitch nodes can either be a *stitch key* (undirected) or *relationship* (directed). A unique *stitch value* is associated with each stitch key such that it forms a clique. Figure 1 shows an instance of a connected component of a stitch multigraph with overlapping cliques.

A connected component in the stitch multigraph represents the basic unit of work for ER. While the majority of connected components are of reasonable sizes (e.g., 20 to 50 stitch nodes), the real challenges center around effective strategies for handling very large connected components—or also commonly known as *hairballs* [12]. For example, the current version of the INXIGHT DRUGS resource has a hairball close to 30,000 stitch nodes spanning across 15 data sources. Developing strategies to untangle large hairballs is the primary challenge for STITCHER.

Equivalence classes in a connected component are explicitly represented as *sgroup nodes* in the stitch multigraph. Entities that share a common *sgroup* node are considered equivalent. There can be multiple instances of sgroup nodes for a given stitch node, with each instance perhaps reflects a specific algorithmic strategy or version. Figure 1 shows that there is only one equivalence class as determined by the underlying ER algorithm for the given connected component.

Stitch keys

Stitch key is a core concept in STITCHER. It defines how entities are matched, which, in turn, determines how cliques and connected components are formed. By virtue of its importance, the stitch key should reflect the true identity of the entity as much as possible. Depending on the entity type, the stitch key can be generic (e.g., synonym) or very specific (e.g., molecular hash key). For drug entity type, STITCHER relies on the following stitch keys for each entity:

`N_Name`. This is the most generic stitch key available. Stitch values associated with this stitch key can be any established names or nomenclature; e.g., tradenames, INN (International Nonproprietary Names), USAN (United States Adopted Names), IUPAC (International Union of Pure and Applied Chemistry).

`I_UNII`, `I_CAS`, `I_CID`, `I_CODE`. These stitch keys represent (i) unique identifiers assigned to the entity by a well-known registrar (e.g., the U.S. Food and Drug Administration in the case of UNII) or (ii) internal company code. `I_UNII`, `I_CAS`, and `I_CID` are specific to drug (or substance in general) entity type, whereas `I_CODE` can be used for any type of identifiers. The decision to map attributes to specific stitch keys over generic ones ultimately rests on the strategies used for ER.

`H_LyChI_L5`, `H_LyChI_L4`, `H_LyChI_L3`. For the small molecule class of drugs, perhaps more important than any identifiers is the underlying chemical structure definition. These stitch keys are hash values derived from the molecular structure at different resolutions [14]. We discuss in detail how these derived stitch values are generated in the next section.

`R_activeMoiety`. Technically not a stitch key, the active moiety relationship between two drugs provides a strong evidence of equivalence. While this relationship can be inferred directly from the chemical structures (e.g., freebase and salt forms, with and without esters), there is some level of curation needed to handle structures with metal complexes and metabolites.

Table 2 shows examples of stitch keys and stitch values for the drug entity IMATINIB MESYLATE. In this example, the `R_activeMoiety` relationship specifies the UNII of the freebase form (IMATINIB) of IMATINIB MESYLATE.

Methods

In general, data integration with STITCHER consists of four basic steps applied in order: *ingestion*, *stitching*, *entity resolution*, and *entity normalization*. With the exception of *entity resolution*, all other steps—as they are currently implemented in STITCHER—are generic and can be applied to a wide range of entity types.

Data ingestion

STITCHER is capable of ingesting data in a wide variety of sources and formats. Semantic formats such as OWL, RDF, and Turtle are supported as are JSON, delimiter separated text, and custom formats. For non-semantic format, a separate configuration file is required to map data attributes to stitch keys.

An important step in data ingestion is the standardization and validation of stitch values. For `N_Name` stitch key, the standardization procedure is simply to convert the input string to uppercase; no validation is performed. For `I_UNII` and `I_CAS` stitch keys, no standardization is required, and validation is a simple checksum calculation to ensure the stitch value is proper. Depending on the input format, STITCHER also provides basic utilities (e.g., regular expression) to help with data transformation during ingestion.

Perhaps the most unique feature of STITCHER is its ability to incorporate knowledge of chemical structures into ER. Whereas traditional approaches rely on names and identifiers to determine equivalence substances, STITCHER goes a step further and utilizes the underlying chemical structures to infer equivalence. This is particularly relevant when the drug is a mixture, prodrug, or active moiety with complex excipient (or derivative thereof). As an example, consider the drug entity IMATINIB MESYLATE and its active ingredient IMATINIB. Here, it is obvious that the two entities cannot be matched by name alone. Instead, having structural information by way of molecular hash keys for each molecular component allows us to determine equivalence from the common active moiety IMATINIB between the two entities. This trivial example might suggest that, instead of comparing names exactly, we find the longest common substring of the names. The approach would certainly work in this example, but to make it work in general would require very specialized parsing rules and dictionaries, e.g., consider an example here where OSELTAMIVIR ACID is an active moiety of the prodrug OSELTAMIVIR.

For data sources with chemical structures, the most computationally demanding step in data ingestion is the generation of molecular hash keys. Hash keys are generated for each component of a chemical structure in three different structural levels: `L5`, `L4`, and `L3`, which correspond to stitch keys `H_LYCHI_L5`, `H_LYCHI_L4`, and

`H_LYCHI_L3`, respectively. Level `L5` is the most specific; it represents the chemical structure as-is, i.e., without structure normalization and standardization. With the exception of the relation `R_activeMoiety`, a match at this level has higher priority over other stitch keys. The next level `L4` represents the structure after normalization and standardization per the LyChI software package [14]. A match at this level implies that two structures are equivalent in terms of stereochemistry, resonance, and tautomer. And the last level `L3` is the same as `L4` but without stereochemistry. A match at this level is considered weak and does not constitute equivalence without other significant supporting evidence. The purpose for `L3` is in anticipation of incorrect or missing stereo information, which is one of the most common type of errors associated with chemical structures. For each hash key, a suffix `-M`, `-S`, or `-N` is also assigned to designate the molecular component as either a *metal*, *salt*, or *neither*, respectively. Table 2 illustrates all three representations for the drug IMATINIB MESYLATE. Note that the cardinality for `L5` is always one, whereas for `L4` and `L3` the cardinality is equal to the number of non-hydrate molecular components. (Hydrate components are removed prior to processing.)

Data stitching

Stitching is the process by which the stitch multigraph is incrementally constructed as data is ingested. Algorithm 1 describes the basic stitching algorithm of STITCHER. This algorithm is applied to each data source, and upon its completion produced a stitch multigraph such that any stitch value that spans N stitch nodes is an induced clique, i.e., a complete subgraph of N nodes and $\frac{N(N-1)}{2}$ edges. Overlapping induced cliques form the basis for the proposed ER approach discussed in the next section. As a side-effect, the stitching algorithm also utilizes the union-find algorithm [13] to efficiently track connected components.

Entity resolution

After all data sources have been stitched together, the next step is to partition the stitch multigraph into disjoint entity sets. Formally, this step is known as *entity resolution* (ER) and is the only step within STITCHER that is specific to the drug entity type. This is to be expected: Given that ER is about adjudicating the splitting and merging of entities, a reasonable amount of knowledge of the entity type is required for the adjudication to be effective. For a given connected component, the iterative process of assigning equivalence labels to stitch nodes is known as *untangling*. Algorithm 2 gives a high level outline of the untangling process.

At the core of the algorithm is the implied priorities associated with the stitch keys. The relation `R_activeMoiety` has the highest priority due to its implied equivalence relation. While it is possible for this relationship to be automatically inferred for specific cases (e.g., salt form and freebase), we currently rely on the data source to provide this semantic annotation. As an example, consider the entities *acetylsalicylic acid* (or also commonly known as *aspirin*) and *ethyl acetylsalicylate* shown in Figure 2. While the two entities have no attributes in common, we know for a fact that *acetylsalicylic acid* is an active moiety of *ethyl acetylsalicylate*. Further examination of the structural differences shows that only an *ester* separates the two entities; per our definition, this falls well within what the FDA considers as equivalent drugs. This example also highlights a predicament: Computationally, there is

nothing to prevent us from imputing active moiety relationships through efficient (sub-) graph isomorphisms. This, however, is a very tempted trap that we have thus far resisted due to other forms of active moiety relationships—e.g., metabolites and metals—that would require considerable investment of effort.

The next priority is the stitch key `I_UNII`. As UNII is the primary identifier issued by the FDA substance registrar, any data source that provides mapping based on this identifier implies that the data source has sufficient knowledge of the FDA's rigorous substance model (i.e., guilt by association). For entities that can be represented by chemical structures, the stitch key `H_LyChI_L4` has the next level of priority. The complexity required for two entities to have the same `H_LyChI_L4` stitch values means that the entities are less likely to match by errors. The rest of the stitch keys (i.e., `N_Name`, `I_CAS`, `I_CID`) all have the lowest priority.

At the completion of Algorithm 2, the disjoint set data structure U contains all equivalence entity classes such that each class is represented by an *sgroup* node in the stitch multigraph. The sgroup nodes are the *resolved entities*.

Entity normalization

The last step in the data integration pipeline is to decide how the resolved entities are defined. This step is referred to as *entity normalization* and its goals are to have (i) clear and consistent strategies for merging attributes and (ii) conflict resolution (semantic as well as self consistency). While this step can be quite trivial if the attributes are mutually exclusive across all data sources, to address this in a general setting will require considerable efforts in terms of understanding the data sources and their metadata. Here, a common strategy is to preferentially choose attributes based on the (perceived) quality of the data sources. For example, considering the example in Table 1. The attributes for the *normalized* entity that corresponds to the equivalence class $\{A_1, A_2, B_1, C_3, D_1, D_3\}$ can simply be the same as those of A_2 because we have reasons to believe data source A is higher quality than other data sources.

Results

With Stitcher serving as the data integration framework, we set out to build a comprehensive resource, InXight Drugs, on drugs that have either been marketed or approved for human use in the United States. Such a resource is not only instrumental for drug repurposing but also serves as a valuable tool to further our understanding of the mechanistic properties of molecular targets [15, 16]. To the best of our knowledge, InXight Drugs is currently the most comprehensive resource of its kind.

Our starting point is the public G-SRS data source from the FDA [17]. This data source is well-curated and contains over 100K substances across six different classes: chemical, structurally diverse, protein, mixture, polymer, and nucleic acid. As a data source derived from the FDA's internal substance registry system [9], the G-SRS data source naturally forms the basis of our data integration effort. Using this data source as the "seed" from which other data sources can map onto has the following benefits:

- Since the G-SRS data source implements the ISO 11238 standard [8] for defining medicinal substances, it serves as an ideal starting point for what constitutes a "drug."
- The data is a public version of the internal substance registry within the FDA; as such, it is well-curated and up-to-date.
- While not complete, the G-SRS data source provides a rich set of active moiety relationships that span salt forms, prodrugs, and metal complexes.

Furthermore, by establishing a reference data source for data integration, we have finer control over the following:

Data quality. A reference data source is typically selected such that it is of high quality. Here, we can also impose other data quality constraints (e.g., no synonyms can span multiple entities) to guide ER.

Data resolution. ER is particularly challenging when data integration involves ontologies. A reference data source can serve as the anchor ontology from which other ontologies can be mapped. As with data quality, we can also impose any additional semantic constraints; e.g., an equivalence class cannot have more than one active moiety.

Data curation. Generating ground-truth data is more manageable with a single data source than across multiple data sources. This is particularly important due to the iterative feedback between data curation and data integration.

While the G-SRS data provides rigous definitions for substances, it lacks other information such as approval status, year, and juridiction, indication, patent, publication, and other uses. The complete list of data sources currently used by Stitcher is shown in Table 5.

Availability

The InXight Drugs resource is available at `https://drugs.ncats.io`. Stitcher and the data integration pipeline developed for the InXight Drugs resource are available in source form at `https://github.com/ncats/stitcher`. The stitch multigraph built with data sources listed in Table 5 is available as a Neo4j database [18] at `https://stitcher.ncats.io/browser`. This database currently contains 192,413 stitch nodes and 11,948,470 edges (relationships and stitch keys). Tables 3 and 4 give a breakdown of the stitch keys and values, respectively, in the stitch multigraph. The complete list of sgroup nodes (i.e., equivalence classes) is available for browsing at `https://stitcher.ncats.io/app/stitches/latest`. All figures and examples used throughout this paper have been generated directly from this database.

Case studies

Aspirin is a versatile drug that can be used alone or in combination with other drugs. Shown in Figure 3 is the induced subgraph of the much larger Aspirin connected component that forms the Aspirin entity. This example demonstrates Stitcher's ability to tease out only the relevant stitch nodes for which Aspirin is likely to be the active moiety for the underlying substance.

Levomethadyl and its derivative Levacetylmethadol are often considered as two separate drugs. This is readily apparent in Figure 4, which shows that there

are two distinct "clusters" in the stitch multigraph. If ER is based on graph metrics (e.g., betweenness centrality), it is likely that this connected component will yield two drugs instead of one. Here, the priority of the stitch key allows the two clusters to be merged to indicate that there is only one drug.

Figure 5 shows the connected component for BENOXAPROFEN, a nonsteroidal antiinflammatory drug approved in 1982. This drug is a racemic mixture. The density of this connected component is a reflection of the lack of specified stereocenter that caused many spurious stitch keys. STITCHER is able to disambiguate the connected component into three distinct entities that represent the mixture, *R*-, and *S*-isomer.

To further illustrate the utility of our approach, we consider how DrugBank 2018 [19] entities are mapped onto the sgroup nodes.

Discussion

Data integration remains a major challenge for drug discovery as biomedical research continues to generate data at an unprecedented rate.

Competing interests

Algorithm 1: Entity stitching algorithm

Let W denote the set of stitch nodes created in the data ingestion step for a given data source D.
Let $\langle k, v \rangle$ be the tuple of stitch key and value, respectively, defined for a stitch node w.
$G = (V, E)$ is the current stitch multigraph.
`Find`(k, v) is a function that returns all stitch nodes in V containing stitch key k and stitch value v.
`Union`(w, z) is a union-find algorithm for tracking disjoint sets (i.e., connected components).

```
for w ∈ W do
    for ⟨k_i, v_i⟩ ∈ w do
        for z ∈ Find(k_i, v_i) do
            E ← E ∪ z ∼ w
            Union(w, z)
        end
    end
    V ← V ∪ w
end
```

Algorithm 2: An algorithm to untangle a connected component

Let U be the disjoint set data structure for all entities.
Let S denote the set of unlabeled entities (i.e., singletons).
$C = (V, E)$ is the connected component.
`MergeNodes`(U, r) is a function that performs transitive closure on stitch nodes in C which are connected by a relation $r \in E$. The results are accumulated in U.
`MergeCliques`(U, K) is a function that takes a set of stitch keys K, finds overlapping cliques that span two or more stitch keys, and performs transitive closure on the entities.
`MergeSingletons`(U, S, K) is a function that also takes in a set of stitch keys K, a set of singleton stitch node S, and find the best mapping to an already labeled stitch node.

```
MergeNodes(U,R_activeMoiety)
MergeNodes(U,I_UNII)
MergeNodes(U,H_LyChI_L4)
MergeCliques(U,N_Name,I_CAS,I_CID,H_LyChI_L4)
MergeSingletons(U, S,N_Name,I_CAS)
```
